Tensions Detected

The value of explicit objectives in search and optimization

Evolution-through-the Search-for-Novelty-Alone.pdf: "Abandoning explicit objectives in favor of searching for behavioral novelty alone can paradoxically outperform objective-based methods. Objective functions often suffer from deception through local optima that prevent reaching the actual objective, with this pathology becoming more severe as objectives become more ambitious. Empirical results in maze navigation and biped walking demonstrate that novelty search significantly outperforms objective-based methods."
Generating Increasingly Complex and Diverse Learning Environments-and-Their-Solutions.pdf and Deliberate-Problem-Solving-with-Large-Language-Models.pdf: "Tree of Thoughts framework maintains explicit goal-directed problem-solving with clear objectives (e.g., solving Game of 24, completing crosswords). The LM explicitly evaluates progress toward these objectives using deliberate reasoning, and search algorithms (BFS, DFS) are guided by these evaluations to reach specific target states. The framework achieves dramatic improvements precisely by maintaining objective-oriented evaluation."

The role of explicit vs. implicit learning mechanisms

Language-Agents-with-Verbal-Reinforcement-Learning.pdf: "Reflexion achieves learning through verbal self-reflection and episodic memory without updating model weights, arguing this is more efficient than traditional weight-updating RL methods which require extensive training samples and expensive fine-tuning. The verbal reflection provides explicit, interpretable guidance for future actions."
Meta-Learning-Representations-for-Continual-Learning.pdf and Model-Agnostic Meta-Learning for Fast Adaptation of Deep Networks.pdf: "OML and MAML achieve efficient learning through explicit weight updates, but to meta-learned representations/parameters that are specifically optimized for fast adaptation. OML meta-learns fixed representations through simulated online updates, while MAML optimizes initial parameters for gradient-based fine-tuning. Both rely on updating network weights as the fundamental learning mechanism."

The necessity of backtracking and exploration in problem-solving

Generating Increasingly Complex and Diverse Learning Environments-and-Their-Solutions.pdf and Deliberate-Problem-Solving-with-Large-Language-Models.pdf: "ToT emphasizes that effective problem-solving requires the ability to explore multiple paths, evaluate them, and backtrack when necessary. Current token-level, left-to-right generation fails precisely because it cannot revise initial decisions. ToT's tree structure enables this exploration and backtracking, which is critical for tasks where early decisions are pivotal."
Evolution-through-the Search-for-Novelty-Alone.pdf: "Novelty search succeeds by never backtracking in behavioral space—it explicitly rewards moving to new behaviors and maintains an archive of all discovered behaviors to prevent revisitation. The approach argues against reconsidering or returning to previously explored regions, instead continuously pushing toward unexplored behavioral territory. Success comes from forward-only exploration that accumulates stepping stones."

NOVEL IDEA 01 · 24% CONFIDENCE

Continual learning systems avoid catastrophic interference when the meta-learning loss landscape's Hessian spectrum partitions into task-specific low-curvature subspaces through eigenvalue repulsion dynamics, with the partition boundary algorithmically determined by the task distribution's Fisher information geometry and failing predictably when inter-task Fisher distances fall below √(d_model/N_samples).

MECHANISM

The causal chain begins with the meta-learning loss landscape geometry. When optimizing $L_{meta}(\theta) = \Sigma_T L_{post\text{-}update}(\theta, T)$ via gradient descent, the parameter trajectory $\theta(t)$ evolves in a landscape whose Hessian H_{meta} encodes all task curvatures simultaneously. At each meta-update step, the gradient ∇L_{meta} pulls θ toward minima of individual task losses, but the curvature tensor H_{meta} determines how these pulls interact. High-curvature directions (large Hessian eigenvalues) correspond to parameter dimensions where small changes cause large loss variations—these are 'fragile' directions requiring careful coordination. The key causal mechanism is eigenvalue repulsion in random matrix ensembles: when $H_{meta} = \Sigma_i w_i H_i$ (weighted sum of task Hessians), the eigenvalue density $\rho(\lambda)$ of H_{meta} follows Marchenko-Pastur statistics modified by inter-task correlations. If task Hessians H_i, H_j share eigenvectors (correlated curvature structures), their eigenvalues cluster, creating high-density regions in $\rho(\lambda)$. But the meta-objective's penalty term $\lambda_{reg}||\theta_{post} - \theta_{pre}||^2$ adds a repulsive Coulomb-like potential $V_{rep} \propto \Sigma_{i\neq j} 1/|\lambda_i - \lambda_j|$ in eigenvalue space. During meta-training, gradient descent on $L_{meta} + \lambda_{reg}||\Delta\theta||^2$ effectively performs simulated annealing in this repulsive potential: eigenvalues spread apart to minimize V_{rep}, dragging their associated eigenvectors into orthogonal subspaces through the eigenvector-eigenvalue coupling $\partial v_i/\partial\lambda_j \propto (H - \lambda_i I)^{-1}(\partial H/\partial\lambda_j)v_i$. This repulsion creates 'avoided crossings' where task-specific curvature directions rotate to minimize overlap rather than merging. The emergent subspace dimensionality $d_{task} = Tr(F_{task})/\lambda_{max}(F_{task})$ arises because Fisher information F_{task} measures the 'effective number' of parameters task T can utilize: high participation ratio (many similar eigenvalues) means task uses many dimensions weakly, low ratio (few dominant eigenvalues) means concentrated usage. The interference-free condition requires $\Sigma_i d_{task,i} < (1-\varepsilon)\cdot d_{model}$ where $\varepsilon=0.2$ is the 'packing inefficiency' from forced orthogonalization. When this bound is violated, spectral repulsion cannot create non-overlapping subspaces, causing unavoidable gradient interference scaling as the subspace overlap integral $\int \rho_i(\lambda)\rho_j(\lambda)d\lambda$.

=

CONCEPT OVERVIEW

The mechanism operates through second-order optimization geometry rather than first-order gradient orthogonality. During meta-learning with objective $L_{meta}(\theta) = E_\tau[L_{task}(\theta + \alpha\nabla L_{task}(\theta))]$, the Hessian $H_{meta} = \partial^2 L_{meta}/\partial\theta^2$ develops a structured spectrum through curvature-mediated eigenvalue repulsion. Specifically, for each task τ_i, the task-specific loss L_i induces a Hessian H_i with dominant eigenvectors $\{v_{i,k}\}$ corresponding to directions of high curvature (large eigenvalues $\lambda_{i,k} > \sigma^2/\alpha$ where σ^2 is gradient noise variance). The meta-objective's penalty on $||\theta_{post} - \theta_{pre}||^2$ creates a repulsive potential between these task-specific curvature directions: when two tasks would share a high-curvature direction ($\langle v_{i,k}, v_{j,m}\rangle > 0.5$), the meta-gradient ∇H_{meta} actively rotates the Hessian eigenbasis to decorrelate them, reducing the inner product to < 0.3. This occurs because shared high-curvature directions would force large parameter movements during adaptation (violating the meta-objective's preference for small $\Delta\theta$), creating selection pressure for spectral separation. The effective dimensionality of each task's subspace d_{task} emerges from this repulsion process: $d_{task} = Tr(F_{task})/\lambda_{max}(F_{task})$ where F_{task} is the Fisher information matrix for task τ, λ_{max} is its maximum eigenvalue, and this ratio measures the 'participation ratio' of meaningful parameter dimensions. When tasks are sampled from a distribution $P(\tau)$ with characteristic inter-task Fisher distance $d_F(\tau_i, \tau_j) \geq \sqrt{(d_{model}/N_{samples})}$, the repulsion dynamics guarantee spectral non-overlap with probability $> 1 - \exp(-d_F^2\cdot N_{samples}/d_{model})$. Below this threshold, tasks occupy overlapping curvature subspaces, causing unavoidable interference that scales as $I(N) \approx (N_{tasks})^2\cdot\exp(-d_F^2\cdot N_{samples}/d_{model})$. The behavioral topology B is constructively derived without free parameters: given task distribution $P(\tau)$ characterized by state-action trajectories $\{s_t, a_t\}$, compute the empirical Fisher information $F_{empirical} = E_\tau[(\nabla\log \pi_\theta(a|s))(\nabla\log \pi_\theta(a|s))^T]$ across all training tasks. Perform eigendecomposition $F_{empirical} = V\Lambda V^T$ and retain eigenvectors $\{v_i\}$ with $\lambda_i > \text{median}(\Lambda)$, defining the behavioral coordinate system as $B = \text{span}(\{v_i\})$. The novelty threshold $\rho = \sqrt{(2d_B\cdot\sigma_{noise}^2\cdot\log(1/\delta))}$ where $d_B = |\{v_i\}|$ is the intrinsic dimensionality, σ_{noise}^2 is the average prediction variance $E_\tau[Var(\pi_\theta(\cdot|s))]$, and $\delta = 0.01$ is the acceptable false-positive rate from concentration inequalities. This construction ensures ρ bounds the statistical distinguishability of behaviorally distinct states. Critically, the theory predicts deterministic failure when: (1) Task diversity is insufficient: $d_F(\tau_i, \tau_j) < \sqrt{(d_{model}/N_{samples})}$ for >10% of task pairs, causing $I(N) > 0.5$ regardless of architecture. (2) Curvature heterogeneity: $\max_i \lambda_{max}(H_i)/\min_j \lambda_{max}(H_j) > d_{model}$, preventing eigenvalue repulsion from establishing stable partitions. (3) Non-stationarity rate: if task distribution drift $\partial P(\tau)/\partial t$ exceeds $(\sigma_{noise}^2/d_{model})\cdot N_{samples}^{-1}$, Fisher geometry updates faster than Hessian spectrum can re-equilibrate. Conversely, it predicts success when these conditions are violated even with poor hyperparameter choices, because the spectral structure is determined by task geometry, not tuning.

Epistemic Audit Trace

THE EPISTEMOLOGIST

Score: 35/100

This hypothesis exhibits sophisticated mathematical machinery but conflates mathematical convenience with physical necessity. The core claim—that gradient orthogonality prevents interference—is explanatorily shallow because it merely restates the problem in geometric language without explaining WHY neural networks should respect linear independence in this way. A Deutschian analysis reveals critical weaknesses: Lack of Hard-to-Vary Structure: The mechanism is highly flexible. If gradient orthogonality failed empirically, one could substitute 'approximate orthogonality', 'block-diagonal structure', or 'low gradient correlation' without changing the predictive framework. The specific dimensionality formula d_task ≈ log(N_params)/log(N_tasks) from random matrix theory is borrowed, not derived from the learning dynamics—changing it to d_task ≈ sqrt(N_params)/N_tasks wouldn't collapse the theory, just shift hyperparameters. Instrumentalist Red Flags: The hypothesis predicts observable correlations (orthogonal gradients → less interference) but doesn't explain the generative reality underneath. WHY does meta-learning create orthogonal subspaces rather than, say, hierarchical dependencies? The appeal to 'penalizing gradient overlap' is circular—it describes the objective function humans designed, not an emergent property of learning itself. The pre-specified behavioral topology B is admitted to fail if 'chosen post-hoc', revealing the framework requires careful human curation to work—a sign of instrumental tuning rather than capturing deep structure. Missing Reductionist Foundation: The mechanism jumps from optimization objectives to emergent geometry without connecting to the physics of gradient descent, the information theory of generalization, or the computational substrate. There's no explanation of how second-order drift 'accumulates' beyond mathematical formalism—what is the physical/computational process that makes quadratic terms dominate? The Crucial Experiment: The proposed test isolates whether the geometric structure (orthogonality) is actually doing causal work, or whether it's an epiphenomenon of other factors (learning rate schedules, capacity, task diversity). If performance is invariant to the internal geometric organization while preserving only surface-level orthogonality metrics, the 'explanation' reduces to 'systems that avoid gradient overlap avoid interference'—a tautology. Verdict: This is a well-constructed predictive model with testable mathematics, but it lacks the explanatory reach of Deutsch's paradigm. It doesn't tell us why continual learning systems must organize this way, only that IF they achieve certain geometric properties, THEN we observe certain outcomes. A deeper explanation would derive gradient orthogonality from more fundamental principles (information bottleneck, thermodynamic efficiency, Kolmogorov complexity) rather than positing it as a design choice.

THE SKEPTIC

Score: 3/100

This hypothesis exhibits fatal Texas Sharpshooter and circular reasoning. The 'pre-specified behavioral topology B' does all the causal work but its determination is left undefined, allowing post-hoc rationalization. Failure modes are escape clauses ('B chosen post-hoc,' 'ρ adjusted after deployment') that define away counterexamples rather than making risky predictions. The gradient orthogonality claim lacks derivation - the meta-objective penalizes gradient magnitude, not overlap between acceptance/rejection subspaces. The random matrix theory dimensionality bound is decorative mathematics borrowed from different contexts without justification. Critically, the theory is unfalsifiable: success validates 'correct pre-specification,' failure indicates 'post-hoc choice' - both determined retroactively. A genuine theory would provide a constructive procedure for deriving B from task properties, predict when this procedure succeeds/fails, and risk refutation. Instead, this wraps a tautology ('correct characterization works') in technical language. The ε-net coverage (step 6) assumes what it should derive: that B captures the geometry of true failure modes. Without independent specification of B, this is self-fulfilling instrumentalism.

Texas Sharpshooter | Confirmation Bias | Post-hoc Theory Fitting

SOVEREIGN VERDICT

REJECTED (42/100)

REFINEMENT APPLIED

- Provide a constructive algorithm for deriving behavioral topology B from task distribution properties alone, without observing failures first. Specify: Given task family T with measurable properties $\{X_1, X_2 ... X_n\}$, $B = f(X_1, X_2 ... X_n)$ where f is fully specified.
- Derive (not assert) why the meta-objective $\sum_i L(\theta, D_i) + \lambda||\nabla L_task||^2$ produces orthogonal acceptance/rejection subspaces rather than merely low-norm gradients. Show this mathematically from the optimization dynamics, not as assumption.
- Replace the borrowed random matrix bound with a derived result specific to meta-learning: prove under what conditions gradient descent on the meta-objective creates approximately orthogonal task subspaces, yielding d_task bounds from first principles.
- Make the theory risky: Specify 3 task distribution scenarios where the theory predicts failure even with 'correct' application, and 3 where it predicts success. These must be prospectively testable, not post-hoc classifications.
- Eliminate the escape clause around ρ drift: Either prove second-order accumulation is negligible under specified conditions (learning rates, curvature bounds), or provide computable warning signals that predict when drift will cause catastrophic failure before it occurs.
- Reformulate the crucial experiment to test the irreducible core: Does the meta-learning objective itself causally produce orthogonal structure, or is orthogonality an artifact of other factors (regularization, capacity, initialization)? Propose ablations that isolate the meta-gradient's contribution.
- The explanation is too 'loose'. Tighten the mechanism so that slight changes would falsify it.
- Move from 'Prediction' to 'Explanation'. Why exactly does this happen at the fundamental level?.

Implementation Approach

Adaptive Learning Lanes: Teaching AI Systems Multiple Skills Without Forgetting

EXECUTION PLAN

PROBLEM STATEMENT

> When artificial intelligence systems learn new tasks, they often forget what they previously learned—a problem called catastrophic forgetting. This makes it difficult to build AI that can continuously adapt to new situations while maintaining performance on earlier tasks. Current solutions require extensive trial-and-error tuning and still fail unpredictably. We need a principled way to determine when an AI can successfully learn multiple tasks and when it will inevitably fail, based on measurable properties of those tasks rather than guesswork.

PROPOSED SOLUTION

This approach treats the AI's internal learning structure like a highway system with dedicated lanes for different tasks. Just as cars traveling at different speeds need separate lanes to avoid collisions, different tasks need separate 'learning lanes' in the AI's parameter space. The solution automatically discovers how many lanes are needed and assigns tasks to appropriate lanes by analyzing the mathematical structure of how the AI changes when learning each task. It measures the 'distance' between tasks to determine if they can share resources or need isolation. Most importantly, it provides upfront criteria to predict success or failure: if tasks are too similar (measured by specific distance thresholds), the system will mathematically prove interference is unavoidable, preventing wasted training effort.

IMPLEMENTATION STEPS

01 **Establish Task Distance Measurement Infrastructure**

Build a measurement system that calculates how different each task is from others using Fisher information distance. For each task, collect sample data showing what decisions the AI makes in different situations. Compute how much the AI's behavior would need to change to master each task by tracking sensitivity of outputs to parameter changes. Store these measurements in a task relationship matrix that quantifies the behavioral distance between every pair of tasks. This creates the foundation for determining which tasks can coexist and which will interfere.

02 **Calculate Critical Diversity Threshold**

Determine the minimum distance tasks must have to avoid interference using the formula: threshold equals the square root of (model complexity divided by available training samples). Model complexity is the number of adjustable parameters in your AI system. Count your training samples for each task. Calculate this threshold value—it represents the boundary below which tasks will definitely interfere with each other. Compare all task pairs from Step 1 against this threshold to create a red-flag list of problematic task combinations.

PREREQUISITES: Establish Task Distance Measurement Infrastructure

03 **Perform Pre-Training Feasibility Analysis**

Before committing resources to training, analyze whether success is mathematically possible. Check three conditions: First, verify that fewer than ten percent of task pairs fall below the critical threshold from Step 2. Second, measure the learning difficulty range across tasks—if the hardest task is more than a thousand times harder than the easiest (measured by largest curvature ratios), the system cannot balance them. Third, if working with changing task requirements over time, verify the change rate is slower than your measurement update capability. If any condition fails, document the specific barrier and either acquire more training data, reduce model complexity, or redesign the task set before proceeding.

PREREQUISITES: Calculate Critical Diversity Threshold

04 **Construct the Behavioral Coordinate System**

Create a reference frame that captures the essential ways tasks differ from each other. Take the task distance measurements from Step 1 and decompose them into independent directions of variation—like finding the principal axes that explain how tasks differ. Keep only the directions that account for meaningful differences (specifically, those exceeding the median importance value). This gives you a simplified map where each task occupies a position, and the number of dimensions in this map represents how many independent 'learning lanes' your system needs. Label these dimensions for interpretability—they often correspond to recognizable skill categories.

PREREQUISITES: Establish Task Distance Measurement Infrastructure

04 Construct the Behavioral Coordinate System

Create a reference frame that captures the essential ways tasks differ from each other. Take the task distance measurements from Step 1 and decompose them into independent directions of variation—like finding the principal axes that explain how tasks differ. Keep only the directions that account for meaningful differences (specifically, those exceeding the median importance value). This gives you a simplified map where each task occupies a position, and the number of dimensions in this map represents how many independent 'learning lanes' your system needs. Label these dimensions for interpretability—they often correspond to recognizable skill categories.

PREREQUISITES: Establish Task Distance Measurement Infrastructure

05 Implement Curvature-Aware Meta-Learning

Design the training process to actively separate tasks into distinct learning lanes. Use a meta-learning approach where the system learns how to learn by practicing on sample tasks. The key modification: add a penalty that discourages tasks from using the same high-sensitivity parameters. When the system detects that two tasks would both cause large changes in the same parameters, automatically adjust the learning process to rotate their influence into different parameter subsets. Monitor the overlap between task-specific sensitive directions during training—successful separation shows as overlap dropping below thirty percent. This happens automatically through the optimization dynamics, not through manual intervention.

PREREQUISITES: Construct the Behavioral Coordinate System, Perform Pre-Training Feasibility Analysis

06 Set Up Spectral Monitoring and Alerts

Create a real-time dashboard that tracks the internal structure of your AI's learning geometry during training. Specifically monitor: the separation between task-specific learning lanes (eigenvalue spacing), the effective dimensionality being used by each task, and the overlap between sensitive parameter directions across tasks. Set automatic alerts when overlap exceeds thirty percent between any task pair, when effective dimensionality for a task exceeds available model capacity, or when the spectral structure shows instability (rapid fluctuations). These indicators provide early warning of impending catastrophic forgetting before performance degrades.

PREREQUISITES: Implement Curvature-Aware Meta-Learning

07 Establish Adaptive Novelty Detection

Build a system that determines when new tasks are too similar to existing ones, risking interference. Using the behavioral coordinate system from Step 4, calculate a novelty threshold based on the intrinsic dimensionality, measurement noise levels, and acceptable false-positive rate (typically one percent). When a new task arrives, project it into the behavioral coordinate system and measure its distance to all existing tasks. If any distance falls below the threshold, flag the task as requiring either more training data to increase the critical threshold, or explicit merging with the similar task rather than treating it separately.

PREREQUISITES: Construct the Behavioral Coordinate System, Calculate Critical Diversity Threshold

08 Validate Partition Stability and Document Capacity Limits

After training, verify that the task separation is stable and document the system's capacity. Test by attempting to learn the tasks in different orders—stable partitioning should show similar performance regardless of order. Measure the total number of effective learning lanes the system has created and compare against the model's total capacity. Document the maximum number of tasks supported before interference becomes unavoidable. Create a capacity report showing: current utilization, remaining capacity for new tasks, minimum distance requirements for new tasks, and predicted interference if capacity is exceeded. This provides clear operational boundaries for deployment.

PREREQUISITES: Set Up Spectral Monitoring and Alerts, Establish Adaptive Novelty Detection

RISKS & MITIGATIONS

Insufficient training data causes the task distance measurements to be unreliable, leading to incorrect feasibility predictions. Small sample sizes create high variance in Fisher information estimates.

MITIGATION: Establish minimum sample size requirements before beginning: require at least ten times the model dimension in samples per task. Use bootstrap resampling to estimate measurement uncertainty and widen safety margins when uncertainty is high. If data is limited, reduce model complexity rather than proceeding with uncertain measurements.

Tasks evolve over time in deployment, causing the behavioral coordinate system and task distances to become outdated. The system was optimized for the original task distribution but now faces different requirements.

MITIGATION: Implement continuous monitoring of task distribution drift by tracking prediction variance on held-out validation sets. When drift rate exceeds the calculated threshold (noise variance divided by model dimension times sample size), trigger a retraining cycle to update the behavioral coordinate system. Maintain a buffer of recent task samples to enable rapid recalibration.

The approach assumes tasks are well-defined and stationary during the analysis phase. In reality, task boundaries may be ambiguous or tasks may have hierarchical structure not captured by distance metrics.

MITIGATION: Begin with conservative task definitions that are clearly separated, then progressively test boundary cases. Use hierarchical clustering on the task distance matrix to discover natural task groupings. When task boundaries are ambiguous, treat ambiguous cases as separate tasks initially—the spectral analysis will reveal if they can be merged based on measured overlap rather than assumptions.

Computational cost of calculating full Fisher information matrices and Hessian eigendecompositions scales poorly with model size, potentially making the approach impractical for very large models.

MITIGATION: Use efficient approximations for large-scale models: randomized eigenvalue estimation, block-diagonal approximations for structured architectures, or low-rank Fisher matrix estimates. Validate approximations on smaller model versions first. For extremely large models, apply the analysis to critical subnetworks or layers rather than the entire parameter space.

The mathematical conditions may be too conservative, rejecting task combinations that would actually succeed in practice, leading to underutilization of model capacity.

MITIGATION: Treat the theoretical thresholds as initial guidelines rather than absolute barriers. When conditions are marginally violated (within twenty percent of threshold), run small-scale pilot experiments to measure actual interference. Calibrate safety margins based on empirical results in your specific domain. Document cases where the theory was overly conservative to refine future predictions.

The approach requires expertise in advanced mathematical concepts to implement correctly, creating a knowledge barrier for practical deployment.

MITIGATION: Develop packaged software tools that automate the mathematical computations and present results through intuitive visualizations. Create decision flowcharts that map measurement results to actionable recommendations without requiring deep theoretical understanding. Provide reference implementations with extensive documentation and worked examples for common scenarios.

SUCCESS METRICS

- Prediction accuracy: The pre-training feasibility analysis correctly predicts success or failure in at least ninety percent of cases, measured by comparing predicted interference levels against actual performance degradation after training.
- Interference reduction: Systems trained with curvature-aware meta-learning show at least fifty percent less catastrophic forgetting compared to standard continual learning baselines, measured by retention of performance on early tasks after learning later tasks.
- Capacity utilization: The approach enables training on at least twice as many tasks before hitting interference limits compared to existing methods, measured by the maximum number of tasks achievable while maintaining ninety percent of single-task performance levels.
- Spectral separation quality: Task-specific learning directions show less than thirty percent overlap after training, measured by inner products between dominant eigenvector sets for each task pair.
- Threshold calibration accuracy: The calculated critical distance threshold correctly identifies problematic task pairs, with false positive rate below five percent and false negative rate below ten percent when validated against held-out task combinations.
- Computational efficiency: The measurement and monitoring overhead adds less than twenty percent to total training time compared to baseline meta-learning, making the approach practical for production use.
- Generalization to new tasks: When new tasks arriving after initial training have measured distances above the novelty threshold, they integrate successfully with less than ten percent performance degradation on existing tasks.
- Interpretability value: The behavioral coordinate system dimensions correspond to recognizable task characteristics in at least seventy percent of cases based on human expert review, providing actionable insights beyond just numerical predictions.
